

Presidential Elections and Cryptocurrency Returns: Evidence from 2020 and 2024

Haoyu Zhai*

February 17, 2026

Abstract

How do cryptocurrency prices respond to major political events? Focusing on the two most recent U.S. presidential elections (2020 and 2024), we use an event-study design to document sharply different dynamics in election-induced abnormal returns. Adjusting individual cryptocurrency returns by a market-wide index, we find similar anticipatory declines of 5–10% beginning approximately one week before Election Day in both elections. Post-election dynamics diverge sharply: returns remained depressed in 2020, reaching –10 to –15% one month after the election, while reversing strongly in 2024 to exceed +30% over the same horizon. Results are robust to alternative specifications and market proxies. We link the contrasting post-election trajectories to differences in pre-existing market sentiment and expectations about incoming regulatory policy toward the cryptocurrency sector. The divergent price trends appear consistent with the resolution of electoral and policy uncertainty in a changed context of policy projections. Our comparative evidence complements existing findings and extends the empirical literature on political economy and finance.

1 Introduction

Do cryptocurrency prices respond to political events? Recent work in finance and political economy has examined the financial consequences of major political shocks in this emerging asset class, with particular attention paid to U.S. presidential elections. Existing studies document a range of market responses, including abnormal returns, excess volatility, herding, and spillover effects (Bouoiyour et al., 2019; Ben Jabeur et al., 2025; de Almeida et al., 2026; Pirazzi Maffiola and Sevim, 2026; Wei et al., 2026). This focus reflects both the global influence of U.S. financial markets and the well-documented role of electoral and policy uncertainty in shaping asset prices in traditional markets, especially equities (Santa-Clara and Valkanov, 2003; Snowberg et al., 2007; Pástor and Veronesi, 2020; Mnasri and Essaddam, 2021). At the same time, the cryptocurrency sector has expanded rapidly—from below USD 1 trillion in early 2018 to around USD 3 trillion by the mid-2020s in

*New York University Abu Dhabi. hz3803@nyu.edu.

aggregate market capitalization¹—and has become increasingly exposed to U.S. regulatory and executive policy, making market responses to presidential elections particularly salient.

Most empirical studies of electoral effects on cryptocurrency prices focus on a single recent election, typically 2020 or 2024, reflecting both the sector’s late maturation (Borri and Shakhnov, 2022; Borri et al., 2025) and the event-study nature of election-based designs. While such approaches provide clean identification around specific political shocks, they limit comparative inference across policy environments. In this study, we retain a recent-time design for data quality reasons but adopt a two-election framework, examining market responses to both the 2020 and 2024 U.S. presidential elections. This comparison is informative because the two elections differ sharply in party-policy positioning toward cryptocurrency. In 2020, neither major-party candidate articulated a clearly supportive stance toward the sector. By contrast, the 2024 election featured sustained pro-crypto messaging by the Republican candidate—who subsequently won the presidency—creating a salient policy asymmetry between the parties (Rogers et al., 2024; Wei et al., 2026). Comparing price dynamics across these two elections allows us to better separate responses to electoral uncertainty from those driven by policy expectations, within the constraints imposed by the sector’s short historical record.

Our event-study analysis reveals markedly different market reactions across the two elections. In both cases, we observe pre-election declines in daily cryptocurrency returns beginning approximately 10–15 days before Election Day. Following the 2020 election, returns remained depressed well into the post-election period, with negative cumulative abnormal returns persisting for roughly one month after the outcome was called. In contrast, the 2024 election was followed by a sharp and sustained increase in returns starting shortly after Election Day and continuing through the subsequent month. Estimated cumulative abnormal returns fell to approximately –10 to –15% in 2020 but rose to around +10 to +30% in 2024. These patterns are robust across alternative model specifications, event windows, and measurement choices.

Our 2024 findings are consistent with Pirazzi Maffiola and Sevim (2026), whose analysis is closest to ours but focuses on a single election. Drawing on market sentiment indicators and documented policy positions, we interpret the divergence in post-election returns as reflecting expectations about the regulatory environment facing cryptocurrency under the incoming administration. While the common pre-election decline likely reflects a mixture of electoral and policy uncertainty, the sharply divergent post-election trajectories suggest rapid incorporation of policy signals once uncertainty is largely resolved. Taken together, our results contribute comparative evidence on how political events and policy expectations shape investor behavior in emerging financial markets.

2 Data and Methods

2.1 Data

Cryptocurrency returns. We begin with daily price data for the top 250 cryptocurrencies by recent market capitalization, sourced from Yahoo Finance and CoinGecko via publicly available APIs, with coverage beginning in September 2014.² We define the event date as Election Day in each presidential election (November 3, 2020, and November 5, 2024) and extract the sample from a window covering approximately one year before and one year after the election, defined using complete calendar weeks. To ensure a consistent sample composition and avoid endogenous entry or exit around the event, we retain only tokens with complete price coverage over the full window for each election. Following standard practice, we further exclude observations with non-positive closing prices or trading volumes (Borri et al., 2025). After filling occasional within-series gaps using last-observation-carried-forward interpolation—which we verified affected fewer than 1% of observations—these inclusion criteria yield 64 tokens (48,256 observations) for the 2020 election and 126 tokens (95,004 observations) for the 2024 election, each spanning an identical window of 754 calendar days.

Market returns. As a proxy for aggregate market performance, we use the S&P Cryptocurrency Broad Digital Asset (BDA) Index, constructed by S&P Global.³ The index tracks a broad set of digital assets listed on recognized open exchanges and subject to minimum liquidity and market capitalization requirements. We apply the same sampling window and preprocessing steps as for the individual tokens, yielding a matched series of 754 daily observations for each election sample.

For both individual tokens and the market index, we compute daily log returns as log differences of consecutive closing prices. Augmented Dickey–Fuller (ADF) tests reject the null of a unit root for all return series at the 1% level. Summary statistics for the election-specific samples are reported in Appendix Tables A1 and A2.

2.2 Empirical Strategy

Our empirical design follows the standard event-study methodology widely used in the finance and economics literature to study the timing and impact of discrete shocks on financial markets (MacKinlay, 1997; Linton, 2019). For individual asset (token) i at event time t , we define abnormal returns as

$$AR_{it} = R_{it} - \mathbb{E}(R_{it} | X_t), \quad (1)$$

²The up-to-date dataset is available on Kaggle at <https://www.kaggle.com/datasets/isaaclopgu/cryptocurrency-historical-prices-top-100-2025>.

³Index overview available at <https://www.spglobal.com/spdji/en/indices/digital-assets/sp-cryptocurrency-broad-digital-asset-bda-index/#overview>.

where AR_{it} , R_{it} , and $\mathbb{E}(R_{it} | X_t)$ denote abnormal, observed, and normal (expected) returns, respectively, and X_t represents the conditioning information set for the normal return model. We adopt the standard market model, which relates individual asset returns linearly to aggregate market returns:

$$\mathbb{E}(R_{it} | X_t) = \alpha_i + \beta_i R_{mt}, \quad (2)$$

where R_{mt} is the return on the market portfolio at time t , and α_i and β_i capture asset-specific baseline returns and market exposure, respectively. Including market returns allows us to account for market-wide fluctuations that affect all assets and to isolate abnormal performance at the token level. Individual token returns and market returns are measured using the cryptocurrency price data and the S&P Cryptocurrency BDA Index described above.

Our primary object of interest is the cumulative abnormal return (CAR) for token i over a window from T_1 to T_2 , defined as

$$CAR_i(T_1, T_2) = \sum_{t=T_1}^{t=T_2} AR_{it}. \quad (3)$$

CARs capture the cumulative (log) price change over the event window relative to a normal-return benchmark. Following Pirazzi Maffiola and Sevim (2026), we consider both a short event window of ± 10 days and a longer window of ± 30 days around Election Day in each presidential election. This two-window design allows us to distinguish immediate market reactions from more persistent post-election adjustments as information is gradually incorporated into prices. Expected returns are estimated using a market model fitted over a pre-election estimation window, and we compute market-adjusted CARs for each day within the event window, constructing 95% confidence intervals using bootstrap standard errors.

3 Main Findings

Table 1 and Figure 1 report our main results in numerical and graphical form. For ease of interpretation, we back-convert log CARs to percentage terms. Market-adjusted abnormal returns become negative at least five days before Election Day, likely reflecting uncertainty about electoral and policy outcomes. These losses persisted through Election Day for both elections, but were smaller in magnitude in 2024 (-3 to -5%) than in 2020 (-6 to -15%).

Post-election dynamics diverged sharply. In 2020, abnormal returns continued to decline, reaching -13 to -16% within 10–15 days after Election Day. In contrast, returns in 2024 reversed strongly, rising to $+7$ to $+30\%$ over the ± 30 -day window. The full-series plots place these point estimates in broader context, highlighting similar pre-election patterns but markedly different post-election trajectories: upward CARs in 2024 versus a stabilizing downward trend in 2020. This contrast

persists across both the ± 10 -day (Panel A) and ± 30 -day (Panel B) windows and becomes more pronounced further from the event date.

Table 1: Cumulative abnormal returns (CARs, percent) at selected event days around the 2020 and 2024 U.S. presidential elections. Entries report market-adjusted CAR means with bootstrap 95% confidence intervals for ± 10 and ± 30 day windows. Negative event days capture pre-election market anticipation; Day 0 denotes Election Day. CARs are normalized to zero on the first pre-event day of each window. This table reports selected days for brevity; full daily trajectories are shown in Figure 1.

<i>Event day</i>	Election 2020				Election 2024

Figure 1: Estimated cumulative abnormal returns (CARs) around U.S. presidential elections. Market-adjusted estimates with bootstrap 95% confidence intervals. Panel A reports a ± 10 -day event window; Panel B reports a ± 30 -day event window. Day 0 denotes Election Day.

Our 2024 results align closely with Pirazzi Maffiola and Sevim (2026), who likewise document significant pre-election declines followed by sharp post-election rebounds. Despite differences in token coverage and event-study design, both studies estimate long-run post-election gains exceeding

+30%. Our short-term reversal occurs one to two days later than in their analysis, likely reflecting differences in the precise timing of event-window construction. By adding evidence from the 2020 election, we further show that cryptocurrency markets respond differentially to similar resolutions of electoral uncertainty, consistent with rapid incorporation of changing policy expectations. Taken together, these patterns suggest semi-strong efficiency in this emerging asset class.

We conduct several robustness checks. Specifically, we (i) use Bitcoin returns as the market proxy (excluding Bitcoin from the estimation sample), (ii) estimate unadjusted CARs, (iii) redefine the event date as the result-call day, and (iv) shorten the estimation window to 120 days. As shown in Appendix Table A3, all alternatives yield qualitatively similar results. The only notable deviation arises under unadjusted CARs, which produce more positive post-election sequences and are less reliable than our preferred market-adjusted specification.

4 Concluding Remarks

The pre- and post-election divergence in abnormal returns unfolds against markedly different sentiment backdrops. As shown in Appendix Tables B1 and B2, the Crypto Fear and Greed Index (FGI)—a commonly used proxy for retail sentiment in crypto markets—starts from a substantially higher baseline in the year preceding the 2024 election (averaging above 60 on the 0–100 scale) than in 2020 (averaging below 50). This elevated sentiment likely reflects, in part, positive market psychology associated with the overtly pro-crypto stance adopted by one of the main-party candidates.

Regression results show that differences in sentiment momentum largely vanish once autoregressive dynamics are accounted for, revealing broadly similar mean-reversion patterns across elections (Table B2). Taken together, these findings suggest that—conditional on relatively slow-moving fundamentals—the resolution of electoral uncertainty in 2024 primarily confirmed pre-existing beliefs about policy orientation toward the cryptocurrency sector, rather than conveying substantial new information. By contrast, sentiment in 2020 evolved from a lower baseline and exhibited more pronounced speculative dynamics in the post-election period.

To summarize, we examine cumulative abnormal returns over 10- and 30-day windows around Election Day in the two most recent U.S. presidential elections using a standard event-study framework. While both episodes feature comparable pre-election anticipatory declines, post-election trajectories differ sharply: we observe persistent excess losses of approximately 15% following the 2020 election, versus excess gains reaching approximately 20% in 2024. We link this conditional divergence to differences in pre-election sentiment baselines, policy-related market expectations, and comparatively muted sentiment adjustments in 2024. Consistent with and extending existing work, our results provide comparative evidence that cryptocurrency markets incorporate political and policy signals in a manner broadly consistent with semi-strong efficiency.

Table B1: Fear–Greed Index around U.S. Presidential Elections

Event window	Election 2020		Election 2024	
	Level	Momentum (%)	Level	Momentum (%)
$(-\infty, -30]$	42.00	-1.15	61.70	-1.06
$(-30, -10]$	55.30	2.51	61.00	0.92
$(-10, 0)$	71.00	-0.74	73.70	-0.38
$\{0\}$	71.00	0.00	70.00	0.00
$(0, 10]$	84.80	1.93	78.30	1.19
$(10, 30]$	90.10	0.06	82.80	0.02
$(30, \infty)$	60.30	-2.24	53.10	-2.30

Notes: Level reports the mean Fear–Greed Index within each event window. Momentum reports the mean daily percentage change in the index. Event windows are defined relative to Election Day (0).

Table B2: Election Effects on Crypto Fear–Greed Sentiment

	Level			Change (%)		
	2020	2024	Comparison	2020	2024	Comparison
Baseline (Pre-Day $(-\infty, -30]$)	1.896*** (0.490)	4.503*** (1.034)	2.369*** (0.424)	-0.014 [†] (0.008)	-0.013 [†] (0.007)	-0.014 [†] (0.008)
